Gateway Function for Network Slicing
draft-homma-nmrg-slice-gateway-00

Abstract

This document describes the roles and requirements for a slice gateway that is a function or function group for handling data plane traffic, such as connecting/disconnecting and compose/decompose network slice subnets and providing network slices from end to end. The interworkings between management and control elements at the management and control planes with the gateway function for controlling and orchestrating end-to-end network slices are also presented in this document.

Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of BCP 78 and BCP 79.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at https://datatracker.ietf.org/drafts/current/.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on April 25, 2019.

1. Introduction

Network slicing is an approach to create separate virtual networks in support of service depending on several requirements on the same physical resources, and it enables networks to adapt to requirements, which is diverse more, inexpensively and flexibly. The overview is introduced in [Slicing_Tutorial] and [NECOS].

It’s also expected to enhance usability of infrastructural networks for tenants and create new business opportunities. For example, by using network slices lent from infrastructure operators, other industrial companies can provide communication services including ensurance of network transport without having physical infrastructure.

From a business point of view, a slice includes a combination of all the relevant network resources, functions, and assets required to fulfill a specific business case or service, including OSS, BSS and DevOps processes.

From the network infrastructure point of view, network slice requires the partitioning and assignment of a set of resources that can be used in an isolated, disjunctive or non-disjunctive manner for that slice.

From the tenant point of view, network slice provides different capabilities, specifically in terms of their management and control capabilities, and how much of them the network service provider hands over to the slice tenant. As such there are two kinds of slices: (A) Inner slices, understood as the partitions used for internal services of the provider, retaining full control and management of them. (B) Outer slices, being those partitions hosting customer services, appearing to the customer as dedicated networks.

Network slices are established with combination of various technologies, such as software defined network (SDN), network function virtualization (NFV), or traffic engineering, and managed/operated with automation technologies such as orchestrator.
Assumed use cases of network slices include establishment of virtual networks whose qualities are guaranteed from end to end under the supervision of multi-domain orchestrators. In such cases, a network slice subnet is created on each domain, such as access network and core network, and an end-to-end network slices is composed of connected subnets.

Network slice subnets are built based on specifications of the underlay network, and thus the used technologies might vary. Therefore, a gateway function, which enables to connect subnets while adapting the differentiations and forward data packets to/from the appropriate next subnet, is required.

This document describes the gateway function for network slicing, called slice gateway or SLG, and the role and requirements are described. Note that defining a new data plane technology is not a goal of this draft. In addition, this draft aims to specify management-related requirements for an SLG, which may be implemented using existing data plane technologies.

2. Definition of Terms

Network Slicing: Network slicing is a technology or an approach to create separate virtual networks in support of services, depending on several requirements, on the same physical resources. This is possible by combinations of several network technologies.

Network Slice (NS): An NS is a virtual network established on network infrastructure. Some include additional network functions such as firewall or load-balancer in addition to basically forwarding functions such as switches or routers. It has an overlay architecture and is independent from the underlay network’s topology.

NS Subnet: An NS subnet is partially virtual network established within a single domain.

End-to-End Network Slice (E2E-NS): An E2E-NS is a virtual network connecting between end points. E2E slices are composed of a single NS subnet or multiple NS subnets.

Network Slice as a Service (NSaaS): An NSaaS is a NS distribution model in which a third-party provider hosts NSs and makes them available to customers.

Network Slice Tenant (NS Tenant): An NS tenant is a person or group that rents and occupies NSs from NS providers.
Domain: A domain is a group of a network and devices administrated as a unit with common rules and procedures.

Administrative Domain: An administrative domain is a group of networks and devices managed by an administrator.

Resource: A resource is element used to create virtual networks. There are several types of resources, i.e., connectivity, computing and storage.

Network Function Virtualization (NFV): NFV is the concept or technologies to provide dedicated network appliances as software.

Software Defined Network (SDN): SDN is the concept or technologies to separate network control plane from data plane, and control network devices dynamically and flexibly.

Virtual Network: A virtual network is a network running a number of virtual network functions.

Virtual Network Function (VNF): A virtual network function (VNF) is a network function whose functional software is decoupled from hardware. One or more virtual machines running different software and processes on top of industry-standard high-volume servers, switches and storage, or cloud computing infrastructure, and capable of implementing network functions traditionally implemented via custom hardware appliances and middleboxes (e.g., router, NAT, firewall, load balancer, etc.)

Slice Gateway Function (SLG): An SLG is a function or a group of functions to connect/disconnect NS subnets. The roles are described in the following sections.

Business Support System and Operation Support System (BSS/OSS): BSS/OSS are systems to support service providing and operation of network devices.

Orchestrator: Orchestrator is an entity to operate network components automatically. There are several types of orchestrators including NFV Orchestrator (NFVO) or service orchestrator defined by ETSI NFV and Open Source MANO (OSM) ([NFV-Architectural-Framework] and [OSM-White-Paper]).

SLG Controller (SLG-Ctrl): An SLG-Ctrl is an entity that controls SLGs. An SLG-Ctrl is controlled by upper-level operation systems such as OSS/BSS or orchestrator.
3. Motivations and Roles of SLG

One of the main roles of SLG is the enablement of interworkings between data plane with management and control elements for controlling and orchestrating end-to-end slices.

Use cases of network slices are discussed in several Standard Developing Organizations (SDOs). Some examples are described in use cases document ([I-D.netslices-usecases]).

In some proposed use cases, an NS is structured across multiple network domains. The capability of NS subnets might be different because the components are domain-specific. In particular, the differentiation in capability between different administrative domains is large.

For connecting some different NS subnets and providing a NS that guarantees the prescribed quality from end to end, SLGs are required to connect such NS subnets. SLGs enable to provide E2E-NSs independently of specifications of underlay networks by hiding the differentiations and connecting between NS subnets. An overview of this concept is shown in Figure 1. SLGs glue NS subnets established on each domain and provide an E2E-NS.
Figure 1: E2E-NS composed of multiple NS subnets

Moreover, identification of user service traffic and their allocation/disallocation to the appropriate NS subnet are required at the edges of E2E-NSs, as shown in Figure 2, and SLGs might take on these roles.

Figure 2: NS subnet selection of SLG
Note that, this model has the assumption that transitions of data packets from one NS subnet to another are executed at only SLGs. Also, an SLG is not necessarily implemented as a single device or virtual machine (VM).

4. Architecture of Network Slicing System

NSs are composed of several (virtual) network functions and links, and the characteristics of each NS are based on the assumed service. Also, some of NSs are deployed across multiple administrative domains. For deploying the appropriate NSs based on each service requirements, a management system, which enables to control network resources totally within a domain, and interaction between such management systems are required.

An SLG is a network function, and SLGs are installed at edge of NS subnets. NSs are dynamically created, deleted, and moved depending on requests from network operator or NS tenants. Therefore, some SLGs would be required to be VNF for flexible deployment.

This section describes overview of NS management system architecture (Section 4.1).

4.1. Network Slice Management System Architecture

The architecture overview of NS management system is shown in Figure 3.
Orchestrators manage whole resources including network elements and server resources (i.e., routing, bandwidth, compute or storage). In this figure, the resources including network elements and server resources are managed by resource orchestrators installed in each domain, and the E2E-orchestrator and network service orchestrator handle resource orchestrators.
NSs are requested from NS tenants via the portal system and the order of creations of an NS is given to the E2E orchestrator from the portal system via BSS/OSS. When an NS across multiple administrative domains are requested, the portal system that received the request forwards the order to create NS subnets to the other infrastructure providers’ systems via Cross-Segment Slice Manager. The details of COMS architecture are described in the architecture document ([I-D.qiang-coms-architecture]).

SLGs are also controlled via orchestrators. An SLG basically belongs to a network element, and it might also belong to server resource if it runs as a VNF. (The position of SLG deployed as a VNF is shown in Appendix B.)

The information model used in this architecture is described in information model document ([I-D.qiang-coms-netslicing-information-model]).

5. Requirements for SLG

An SLG is basically a component in the data plane and has the roles of data packet processing. Moreover, it is required to have functions for control/management processes such as connecting to underlay networks or managing NSs.

Furthermore, an SLG might be required to support handling services provided on NSs in addition to controlling of NS because an SLG is an edge node on an E2E-NS.

In this section, we describe the requirements for an SLG in terms of the following aspects and their interworkings.

1. Data plane for NSs as infrastructure
2. Control/management plane for NSs as infrastructure
3. Data plane for services on NSs
4. Control/management plane for services on NSs

5.1. Management of NS as Infrastructure

5.1.1. Data Plane Aspect
5.1.1.1. Identification/Classification

SLGs at the edge of E2E-NSs MUST have the capability to identify and classify data packets, and assign them to the appropriate E2E-NS. This requirement varies depending on the location.

Fixed Access: An SLG MUST identify and classify data packet with access point, including CPE or WiFi-AP, or subscriber ID such as VLAN-ID. Moreover, in some services, an SLG should identify and classify data packets based on user device or application used in the communication.

Mobile Access: An SLG MUST identify and classify data packet with subscriber-ID such as IMSI, radio-wave bandwidth, or identifier of tunnels. Moreover, in some services, an SLG should identify and classify data packets based on application used in the communication or location of the user equipment (UE).

Between NS subnets: An SLG MUST identify and classify data packet based on the tunnel-ID or virtual routing and forwarding (VRF) that received the packets. If specific slice identifier such as a value mapped in the metadata field of the IP header is used; an SLG should identify and classify data packets with the ID.

5.1.1.2. Transporting/Forwarding

SLGs MUST provide functions for transport data packets depending on the specifications of the underlay networks.

Encapsulation/Decapsulation/Tagging: In network slicing, duplication of IP addresses of user packets between NSs MUST be accepted, thus, using techniques that enable separation of a network logically is preferred. In short, some tunnel protocols or tagging approaches should be used as transport of NSs. For this reason, SLG MUST support encapsulation or tagging of data packets based on the specification of the underlay network. Also, SLG MUST support the packets’ decapsulation or untagging. Examples of tunnel protocols and tags that can be used for creating NSs on L2/L3 segments are described below.

L2 Segment: VLAN, MPLS, Segment Routing MPLS (SR-MPLS), PPPoE, etc.

L3 Segment: GRE, L2TP, GTP-U, VxLAN, IPv6 Segment Routing (SRv6), etc.
VxLAN, SR-MPLS, and SRv6 are described in their specification documents ([RFC7348], [I-D.ietf-spring-segment-routing-mpls], and [I-D.ietf-6man-segment-routing-header]).

Translation of Encapsulation/Tagging Form: SLG MUST support to translate tunnel header or tag of received packets to the appropriate tunnel header or tag when it forwards data packets to the next NS subnet that has different transport capability.

Distribution of Traffic: Some NSs have multiple route between the same end points within the same NS subnet because of traffic engineering, switching to a redundant path, or other reasons, and SLG MAY forward data packets with the appropriate route based on some trigger information. An example of the overview of this requirement is shown in Figure 4. In this figure, there are two routes, main and sub, between SLGs, and an SLG switches forwarding route depending on the network situation such as congestion occurrence on the current route.

![Diagram](image)

**Figure 4: An example of traffic distribution by SLG**

5.1.1.3. Isolation between NSs

In NSaaS, isolation control is required for avoiding an NS being affect by other NSs. Traffic engineering or QoS control is ones of the most fundamental approaches to prevent disturbances between NSs.

Traffic Shaping/Policing: An SLG MUST execute traffic shaping and policing at its egress and ingress ports to avoid an NS using excessive traffic bandwidth.
Quality of service (QoS) Control: If there is an order of priority between NSs on the same underlay infrastructure, an SLG should remark the appropriate QoS parameter of the outer-most header of each packet following the preconfigured setting and provide packet scheduling based on the QoS parameter for providing priority control. The field that SLG refers may vary depending on the specification of the underlay network. For example, COS value is remarked in L2 segments; on the other hand, DSCP value is remarked in L3 segments.

5.1.1.4. Service Chaining as Infrastructural Mechanism(*Optional)

If an SLG is composed of a combination of several components, a service chaining mechanism is required to make them work together and achieve SLG functionality.

Moreover, some NSs may traverse NFVs such as firewalls or cache servers for providing value-added services to their users. In such cases, SLG might be required to support service chaining mechanisms, such as handling of network service header (NSH) defined in [RFC8300]. If an NS includes the service chaining architecture defined in [RFC7665], some SLG would be required to support following functions; classifier(CF), service function forwarder (SFF), and inter boundary node(IBN). (Details of CF, SFF and IBN are described in SFC documents; [RFC7665], [I-D.ietf-sfc-hierarchical].)

5.1.2. Control/Management Planes Aspects

5.1.2.1. Interfaces to Controllers or Operation Systems

SLG MUST have interface to its controller or operation systems for set parameters related to the data plane functions described in Section 5.1.1. In addition, an SLG at the edges of E2E-NSs MUST have interfaces to authentication servers.

5.1.2.2. Address Resolution/Routing

An SLG MUST support address resolution or routing mechanisms to connect to underlay network elements including routers or L2 switches.

5.1.2.3. Authentication Authorization Accounting (AAA)

For preventing entry of irregular traffic to NSs, an SLG at the edge of E2E-NS MUST support AAA mechanism for incoming traffic. Also, when an SLG connects to another SLG in other administrative domain, SLGs should have a mechanism to confirm that the connection is established with the regular processes. For example, an SLG is
required to support authentication of the opponent SLG with key
information indicated from higher-level operation systems.

5.1.2.4. Operation Administration and Maintenance (OAM)

In management of NSs, OAM or monitoring mechanisms for both underlay
and overlay networks is required for SLGs. For an underlay network,
an SLG MUST have OAM functions to confirm connectivity to
interconnect equipment. For an overlay network, an SLG MUST have OAM
functions to confirm connectivity to the some node on the same NS,
and measure the traffic amount of flowing packets on each NS.

5.2. Management of Services on NS (*Optional)

5.2.1. Data Plane Aspect

5.2.1.1. Identification/Classification

In NSaaS, some NS tenants may need delivery of an individual service
to each user, device, or application on the same NS. For such
service deliveries, an SLG might be required to identify and classify
user traffic based on some information such as subscriber ID or
payload of data packets. Also, an SLG should be controllable from
the NS tenant.

5.2.1.2. QoS Control

An NS accommodates several communication devices and SLGs might be
required to have fair queueing mechanisms for maintaining service
quality of each user. Also, different types of service traffic that
have different priorities might coexist on an NS. For example, some
NS providers might provide telephone and internet access services to
their users with an NS. In such cases, SLG might be required to
provide QoS control mechanisms for enforcing priority control based
on service priorities.

These QoS controls are executed depending on the information of inner
packets and are independent of isolation mechanisms as
infrastructure. An SLG might be required to have a hierarchical QoS
control mechanism in case that both QoS controls for services over
NSs and isolation between NSs are required.

5.2.1.3. Steering/Service Chaining (Cooperation with VNFs)

SLG might be required to support steering or service chaining
function for conveying data packets to the appropriate network
functions deployed on an NS based on the classification result and
user's contract information.
5.2.2. Control/Management Planes Aspects

5.2.2.1. Interfaces to Service Management Systems

An SLG might have interfaces to controllers for managing user policies on each NS. Some controllers might be deployed on the same NS. If some controllers are located at external networks, they might require SLGs to have APIs.

5.2.2.2. Collection of Telemetry Information

In an NSaaS, collection of telemetry information of each NS might be required for understanding traffic usage. Thus, an SLG might be required to support to collect and report telemetry information of connected NSs.

6. Deployment of SLG

This section describes considerations related with deployment of SLGs.

6.1. Examples of Components Required to Maintain SLG Functions

For providing E2E-NSs on existing network infrastructures, some components located at boundaries of domains are required to have the same set of functionality as an SLG. Examples of such components in each domain type are described below.

Fixed Network: CPE/HGW, Service Edge, Gateway Router, etc.

Mobile Network: User Equipment, Radio-AP, eNodeB, S/P-GW (TS.36.300-3GPP), etc.

Data Center: Gateway Router, L2 switch, ToR switch, Server, etc.

6.2. SLG Types Depending on Locations on NS

There are mainly three types of SLG for creating E2E-NS across multiple administrative domains. The requirements of each SLG type are listed in Appendix A.

6.2.1. Edge SLG (E-SLG)

This is located at an edge of an E2E-NS, and supports identification, classification and authentication of user traffic in addition to fundamental SLG functions, such as transport and isolation. Also, it might be required to have capabilities for services delivered on an NS.
6.2.2. Inter-Subnet SLG (IS-SLG)

This is located between NS subnets within a single administrative domain and has only fundamental functions. It is not necessarily required if a common transport mechanism in all domains is used.

6.2.3. Inter-Domain SLG (ID-SLG)

This is located between NS subnets established on different domains. It supports authentication for connecting to the opponent SLG in addition to fundamental functions.

6.3. Horizontal Connection

The connection form of an SLG varies depending on which type it is. Examples of horizontal connection forms of each SLG type are described below.

E-SLG: An E-SLG accommodates several hosts and NS subnets. This has a forwarding table of end hosts and insert their packets to the appropriate NS subnet. An overview of this connection is shown in Figure 5.
*Virtual Layer*

```
+-----+  
host#1 ===> |     |  _______________
  |     |  |-->/_______________
  |     |  E-SLG     NS Subnet#1
  |     |  |--/_______________
host#2 ===> |     |  NS Subnet#1
  |     |  |-->/_______________
host#3 ===> |     |  NS Subnet#2
  :     |  |--/_______________
  :     |  
```

*Physical Layer*

```
[UE#1] ------\  /  
[UE#2] ------[Edge]  Domain#1  
[UE#3] ------/  
  :     :  `-------------------
```

Figure 5: Overview of horizontal connection of E-SLG

IS-SLG: An IS-SLG has the role of mediator between NS subnets and passes packets received from an NS subnet to the next one. If transport methods used in each domain are different, the IS-SLG translate packet form to the appropriate one. An overview of this connection is shown in Figure 6.
ID-SLG: An ID-SLG passes data packets to another ID-SLG located on a different administrative domain. Some tunnel established between them in advance may be used for the passing of packets. An overview of this connection is shown in Figure 7.

GW: Gateway Node

Figure 6: Overview of horizontal connection of IS-SLG

Figure 7: Overview of horizontal connection of ID-SLG
6.4. Vertical Connection

There are two patterns of vertical connection of SLGs in the middle of E2E-NSs. The first pattern is that the SLGs accommodate only a set of NS subnets, which are composition of the same E2E-NS. In this pattern, such SLGs are not required to support NS subnet selection, however, establishment of a new SLG is required when a new E2E-NS is created. This might causes extra overheads because of deploying many SLGs.

The other pattern is that such SLGs are acceptable to accommodate multiple NS subnets from each domain. In this pattern, SLGs are support NS subnet selection. On the other hand, this pattern can restrain the number of SLGs. Also, it is easy to provide transit of data packets from an NS subnet to other subnet on the same domain.

The overviews of these patterns are shown in Figure 8 and Figure 9.

Figure 8: Overview of vertical connection of SLG: Separated Pattern

Figure 9: Overview of vertical connection of SLG: Shared Pattern
6.5. Software vs. Hardware

An SLG can be created as either a software or hardware function. NSs are virtual networks created depending on requests from external NS tenants, and thus software would be more compatible with usage for NSs in terms of flexibility or manageability. Moreover, it enables to increase or decrease for each function if SLG is composed of combination of several components. However, it is difficult to provide high performance or sufficient throughput for carrier-grade networks with software function. In addition, it would be difficult to implement sufficient QoS control mechanisms with general servers, because they requires special hardware structures. An example of position of SLG in NFV environment is described in Appendix B.

On the other hand, hardware appliances are able to provide high throughput compared with software. However, they are inflexible in terms of provisioning.

From the above considerations, operators should prepare SLG in appropriate ways depending on their usages or locations.

7. Interconnection between NS subnets

SLG provides interconnectivity between NS subnets. The concept and fundamental framework including the related NS information model are described in subnets interconnection document ([I-D.defoy-coms-subnet-interconnection]).

This section is focused on interconnection between NS subnets established on different administrative domains, and describes considerations related to this condition.

7.1. Pre-arrangement of transport protocols

For interconnection between different administrative NS subnets, pre-arrangement of the transport protocol, which is used to connect between SLGs is required. Orchestration systems indicate the protocol and configuration to each SLG.

7.2. Quality Assurance between SLGs

In addition to establishing connection, quality control of communication is important. SLGs of egress side should execute traffic shaping to prevent some NSs from excessively occupying the link between SLGs. Moreover, some SLGs are connected to several other SLGs that are deployed on the different locations. Therefore SLGs of the ingress side should execute traffic policing to avoid
excessive inflow of traffic into some NSs. The parameters for these controls are pre-configured by orchestration systems.

The above approaches are ones of the simplest ways to provide quality assurance of inter-administrative subnets. If there is stricter isolation request, more considerations would be required.

### 7.3. Secure Interconnection

For connecting networks of different administrators, secure interconnection schemes are required. Especially, in an NSaaS, networks might be connected to several networks, and schemes for ensuring secure connectivity would be more important.

SLGs confirm whether the opponent SLG is regular when it requests to connect, and reject the request if the SLG is not regular. In some cases, SLGs might be confirm whether the inner packets received from the other SLGs are sent from regular users.

### 8. Security Considerations

Requirements and considerations for SLG related to security are described in Section 5 and Section 7.

### 9. IANA Considerations

This memo includes no request to IANA.

### 10. Acknowledgement

The authors would like to thank Li Qiang for her kind review and valuable feedback.

Figure 10: List of Requirements for each SLG
Appendix B. Position of SLG on ETSI NFV MANO

Some SLGs and the controllers are deployed and run on NSs as VNFs. An architecture for managing lifecycle of VNFs is under standardization in ETS NFV MANO.

The mapping of SLG as a VM into ETSI NFV MANO architecture is described in Figure 11. In some cases, SLGs are deployed with container. VNFs are parts of NS compositions and NFV orchestrator would be controlled by upper control entities such as resource orchestrator.
